Family Milichiidae

Diagnosis. Small to very small, greyish black or shining black flies, sometimes with conspicuous silvery dusting. Lower frontoorbital setae inclinate (sometimes reduced or absent); upper frontoorbital setae proclinate or curved outwards. Costa with humeral and subcostal breaks; subcosta entire, but sometimes very thin. Tibiae without preapical setae. Ocellar triangle well developed. Proboscis often elongate; palpi large to very large and setose; vibrissae present, often very thin.

Leptometopa latipes (Meigen, 1830)

Biology. The larvae are coprophagous or saprophagous in the widest sense; living in organic detritus like decaying plants, dung, kitchen refuse and birds' nests. Adult flies may be caught on carrion and dung; some species are associated with ants. Some species even attach themselves to other, predatory Diptera (e.g. Asilidae) or even to Reduviidae or spiders, by which they are transported until a prey is captured. Afterwards they sup the exudations from the wounds of the victim in company of the predator.

General references. Hennig (1937 [general, keys], 1956 [larvae]), Papp (1984d [catalogue]), Papp & Wheeler (1998 [general, key to genera]), Sabrosky (1983 [*Desmometopa*], 1987b [general, key to genera]).

References to Dutch fauna. Beuk & Brake (1996), De Meijere (1940, 1946a).
